ACUTE ONSET FLANK PAIN, SUSPICION OF STONE DISEASE

Expert Panel on Urologic Imaging: Deborah A. Baumgarten, MD, MPH; Isaac R. Francis, MD; Edward I. Bluth, MD; William H. Bush, Jr., MD; David D. Casalino, MD; Nancy S. Curry, MD; Gary M. Israel, MD; S. Zafar H. Jafri, MD; Akira Kawashima, MD; Nicholas Papanicolaou, MD; Erick M. Remer, MD; Carl M. Sandler, MD; David B. Spring, MD; Pat Fulgham, MD.

Summary of Literature Review

Urinary tract stones (calculi) are thought to result from either excessive secretion or precipitation of salts in the urine or a relative lack of inhibiting substances. Men are more commonly affected than women, and the incidence increases with age until age 60. Blacks and children are affected less frequently. Renal calculi tend to be recurrent, and flank pain is a nonspecific symptom that may be associated with other entities; therefore, evaluation with imaging is recommended at the initial presentation [1].

A renal calculus small enough to pass into the ureter may cause blockage of urine flow with distension of the upper urinary tract. Ureteral hyperperistalsis occurs, resulting in acute onset of sharp, spasmodyc flank pain and hematuria. The ureter contains several areas where calculi commonly become lodged, (eg, at the ureteropelvic junction), the iliac vessels, and the ureterovesical junction. The probability of spontaneous passage of a ureteral calculus measuring 5 mm in axial diameter or less is very high. A 10 mm calculus, however, is very unlikely to pass spontaneously. Therefore, the treating physician wants to know the size of the calculus as well as its location and its effect on renal function.

Patients with a suspected diagnosis of renal colic have traditionally been evaluated with urinalysis, plain abdominal radiography (KUB), or excretory urography, commonly referred to as intravenous pyelogram (IVP). More recently, ultrasonography (US), computerized tomography (CT), and magnetic resonance imaging (MRI) have been used.

Radiography

The plain-film of the abdomen may be sufficient to diagnose ureterolithiasis in patients with known stone disease and previous KUBs. The sensitivity of the KUB for ureterolithiasis in other patients is poor. Studies by Roth et al [2] and Mutgi et al [3] found sensitivities of 62% and 58% when the radiographs were interpreted retrospectively. Levine et al [4] correlated the KUB with noncontrast CT (NCT) retrospectively, so that an exact correlation was made between stones on the CT scan and the calcific density on the KUB. A sensitivity of only 59% was found for detecting ureteral calculi on the KUB. Ripolles et al [5] used the KUB as a guide for US evaluation of flank pain. They found 64% sensitivity for detecting ureteral calculi and had 6 false positive cases among the 66 patients evaluated. While the KUB may be a valuable part of the IVP or US evaluation of flank pain, it has a very limited role when used alone, and it should not be used to triage which patient should receive NCT.

Computed Tomography

Since the introduction of the use of helical (spiral) NCT as the initial study in evaluating flank pain by Smith et al [6] numerous investigations have confirmed it to be the study with the highest sensitivity (95%-96%) and specificity (98%) for ureterolithiasis [7-15]. Virtually all stones are radio-opaque, and stone size can be measured accurately in cross-section, aiding in predicting outcome. Stone location, accurately depicted by NCT, has also been associated with spontaneous stone passage rates, with the most proximal stones having a higher need for intervention [16]. Recently, coronal reconstruction of axial CT scans have been shown to more accurately predict stone size in the craniocaudal direction, although this dimension is not critical to estimating the likelihood of stone passage [17]. The degree of perinephric stranding present on the affected side on NCT has also been shown to correlate inversely with the likelihood of stone passage, giving additional prognostic information [8], but this finding has been disputed in other studies [18,19].

The amount of stranding is related to the time after onset of pain and is usually not seen in the first 2 hours following the onset of flank pain. It may take up to 8 hours after the onset of pain to become maximal [20]. Secondary signs such as ureteral dilatation and perinephric stranding allow CT to make a diagnosis of a recently passed stone [11,12].

NCT has been directly compared with the IVP in three series [6,15,21]. NCT was equal to the IVP in diagnosing obstruction and more reliable in diagnosing the presence of nephrolithiasis. NCT is also reliable for diagnosing flank pain due to causes other than ureterolithiasis.

ACR Appropriateness Criteria®

2

Acute Onset Flank Pain

An ACR Committee on Appropriateness Criteria and its expert panels have developed criteria for determining appropriate imaging examinations for diagnosis and treatment of specified medical condition(s). These criteria are intended to guide radiologists, radiation oncologists, and referring physicians in making decisions regarding radiologic imaging and treatment. Generally, the complexity and severity of a patient's clinical condition should dictate the selection of appropriate imaging procedures or treatments. Only those exams generally used for evaluation of the patient's condition are ranked. Other imaging studies necessary to evaluate other co-existent diseases or other medical consequences of this condition are not considered in this document. The availability of equipment or personnel may influence the selection of appropriate imaging procedures or treatments. Imaging techniques classified as investigational by the FDA have not been considered in developing these criteria; however, study of new equipment and applications should be encouraged. The ultimate decision regarding the appropriateness of any specific radiologic examination or treatment must be made by the referring physician and radiologist in light of all the circumstances presented in an individual examination.
[13,21,22] such as appendicitis, diverticulitis, and torsed ovarian masses. NCT is safer than the IVP since it uses no contrast media, is rapid (with the entire study taking minutes), and does not require the technical expertise that US does. When CT is available, it is the best first study in the nonpregnant adult presenting with flank pain likely to be due to stone disease and has been shown to be more cost effective [23].

Concerns over radiation exposure, especially in young stone patients, have led to the development and evaluation of reduced dose regimens [24-29]. Other recent technique refinement has included evaluation of the effect of slice width and overlapping image reconstruction on stone detection [30].

**Intravenous Pyelography**

The IVP is the previous standard study for ureterolithiasis and is still the best investigation if NCT is not available. It provides information regarding site and degree of obstruction, size of stone, and effect of obstruction on renal excretion. This examination has a number of relative contraindications, including renal insufficiency, dehydration, past reaction to iodinated contrast agents, and pregnancy. The availability of nonionic iodinated contrast material has reduced the risk of reaction. It may take several hours for excretion to occur in the presence of acute obstruction, in which case it is more time-consuming than the alternative techniques. Another disadvantage is the inability of the IVP to identify alternative diagnoses.

**Ultrasound**

US is a safe, noninvasive imaging modality that can be used to study the urinary tract effectively. The diagnosis of obstructive urinary tract calculi depends on identification of the offending calculus and concomitant pelvicaliectasis and ureterectasis extending to the obstructing site [31,32]. Because it may take many hours for pelvicaliectasis and ureterectasis to develop, US reportedly will miss over 30% of acute obstructions caused by an urethral stone in patients who are not specifically hydrated for the study. Laing et al [33] and Svedstrom et al [34] detected hydronephrosis in 7 of 20 patients (35%) and 16 of 22 patients (73%), respectively, nonhydrated patients with ureteral calculi. More recently, US has been found to be 100% sensitive for signs of obstruction (hydronephrosis, ureteral dilatation, and/or perirenal fluid) perhaps indicating improvement in US equipment [5]. The use of intrarenal Doppler US improves the detection of early obstruction by evaluating for elevated resistive index (RI) in kidneys with nondilated collecting systems [35,36].

Since KUB is superior to US in detecting ureteral calculi, Dalla Palma et al [37] have recommended a combination of KUB and US. US in these cases is used to detect ureteropelvocaliectasis and then to trace the dilated ureter to a shadowing stone. US can also evaluate the presence and type of ureteral jet (with obstruction the jets are absent, diminished significantly in frequency or a constant slow trickle). In a series of 180 patients, the authors showed a 95% negative predictive value of the KUB/US combination, indicating that IVP was not likely to be helpful if the KUB/US tests are negative. However, IVP was indicated if the KUB/US combination was equivocal or if interventional treatment was anticipated.

Svedstrom et al [34] also performed a comparison of KUB, US, combination of KUB/US, and IVP in 49 patients. The accuracies of KUB (61%) and US (69%) were lower than that of IVP (92%). The accuracy of the combination of KUB/US was 71%, still lower than that of IVP. In an effort to reduce the number of IVP examinations needed, a model was tested in which only patients with negative US results went on to have an IVP. This algorithm showed 93% sensitivity and 79% specificity. The KUB/US combination has also been compared to NCT [5]. In this prospective study of 66 patients, the KUB/US combination had a sensitivity of 79% (vs 93% for NCT) for detecting ureteral stones. All missed cases had spontaneous stone passage, leading the authors to conclude that after a negative KUB/US combination, NCT would not add useful information. They suggest use of NCT in those who fail to respond to conservative management or in those in whom surgery is anticipated. The advantage of US is its lack of ionizing radiation and its ability to show some calculi. For this reason it has been suggested for evaluating stones in pregnant women [38]. Its disadvantages include the need for skilled personnel, its inability to accurately measure the size of the calculus, the need to observe the ureteral jet phenomenon at the ureterovesical junction, and its inability to differentiate dilatation without obstruction from true obstruction [39,40].

**Magnetic Resonance Imaging**

Regan et al [41] applied magnetic resonance urography (MRU) to the evaluation of 23 patients with acutely obstructed kidneys. They found 100% sensitivity for diagnosing obstruction, with perirenal fluid seen in 21 of 23 obstructed kidneys (87%) and in no normal kidneys. The site of the obstruction was seen in 80% of these obstructed kidneys. Round signal voids corresponding to the location of stones on correlative IVPs were seen in 12 of 18 patients with ureteric obstruction caused by a stone. These appearances were nonspecific and were also seen secondary to blood clot or tumor. Zielonko et al [42] examined 60 patients with obstructive uropathy. In the 13 patients with ureteric stones, MRU correctly identified the site of obstruction in 12 (1 stone moved between the MRU and confirmatory imaging). Forty-six percent of the

ACR Appropriateness Criteria® 3 Acute Onset Flank Pain
stones were seen as signal voids against a background of bright urine on T2-weighted images. MRU has been successfully used in pregnant patients with flank pain [43].

Recurrent Symptoms of Stone Disease
In addition to pregnant patients, the patient with known stone disease and recurrent symptoms also presents a challenge. In this setting, the likelihood of stone disease as the cause of flank pain is higher [7], but repeated NCTs raise a concern about excessive radiation exposure. Katz et al [44] examined the issue of radiation exposure associated with repetitive NCT in this setting. In a 6-year period, 5,564 NCTs were performed for renal colic. While the vast majority of patients (96%) underwent 1 or 2 NCTs with an estimated effective dose of 6.5-17 mSv, 176 patients had three or more NCTs with an estimated dose of 20-154mSv. One patient had 18 NCTs over the 6-years! In this setting, every effort should be made to use low-dose NCT. A recent study by Poletti et al found excellent sensitivity (95%) and specificity (97%) for detecting stones with a low-dose protocol (30 mA) compared to a standard-dose protocol (180 mA) in patients with a body mass index (BMI) of <30 [29]. Further, if the patient has persistence of symptoms from a documented stone and repeat imaging is contemplated, a limited NCT of the area of the stone through the bladder could be considered if stone passage is the main question. Alternatively, if the stone can be seen by KUB, a repeat KUB might provide useful information at a much lower dose.

Anticipated Exceptions
NCT is the most rapid and accurate technique for evaluating flank pain. If there is uncertainty about whether a calcific density represents a ureteral calculus or a phlebolith, contrast medium can be injected and the scan repeated for definitive diagnosis. The IVP, which is readily available and is familiar to nonradiologic physicians, is the technique of choice if CT is not available. In pregnant patients with flank pain, US is the best initial study. While a limited IVP has been used to evaluate flank pain in pregnancy when the US study is not diagnostic, MRU has potential utility in diagnosing acute urinary tract obstruction without the use of ionizing radiation. NCT using an ultra-low-dose protocol could also be considered.

Nephrogenic systemic fibrosis (NSF, also known as nephrogenic fibrosing dermopathy) was first identified in 1997 and has recently generated substantial concern among radiologists, referring doctors and lay people. NSF. Current theory links the development of NSF to the administration of relatively high doses (eg, >0.2mM/kg) to agents in which the gadolinium is least strongly chelated. The FDA has recently issued a “black box” warning concerning these contrast agents (http://www.fda.gov/cder/drug/InfoSheets/HCP/gcca_200705HCP.pdf).

This warning recommends that, until further information is available, gadolinium contrast agents should not be administered to patients with either acute or significant chronic kidney disease (estimated GFR <30 mL/min/1.73m²), recent liver or kidney transplant or hepato-renal syndrome, unless a risk-benefit assessment suggests that the benefit of administration in the particular patient clearly outweighs the potential risk(s) [45].
